LETTER - THERAPY

Inadequate response to antiplatelet therapy in Sneddon’s syndrome. Time to re-evaluate management recommendations? 

Dear Editor,

A 46-year-old woman presented with asymptomatic violaceous macules on her skin for over 20 years. She had hypertension and had suffered an ischemic stroke at age 38, currently treated with enalapril, aspirin, and rosuvastatin. Despite these drugs, she had a second ischemic stroke at age 46, causing secondary dysarthria, anomic aphasia, and rightsided hemiparesis. She also had a long history of migraines since her youth and had experienced one miscarriage. The physical exam revealed asymptomatic broken reticulated violaceous macules on her arms, trunk, buttocks, and legs (Figs. 1 and 2).

A wide, deep skin biopsy showed multiple small arteries with thickening of the wall, intimal hyperplasia, stenosis, and lumen obliteration, with secondary signs of re-tunneling and neo-vascularization in the reticular dermis and subcutis (Fig. 3).

Cerebral magnetic resonance angiography revealed infarcts in the left frontal insular, right parietal and right posterior inferior cerebellar areas and parenchymal sequelae in the territory irrigated by the right and left medial cerebral artery. Echocardiogram and 24-h Holter electrocardiography were normal. Prothrombin time was 65%, INR 1.38, ANA 1/80 speckled pattern. Anti-DNA, anti-ENA, ANCA and Antiphospholipid (APL) antibodies were negative. Thrombophilia testing revealed Protein S deficiency. A Sneddon Syndrome (SS) APL (-) with Protein S deficiency was diagnosed, and rivaroxaban was initiated.

SS is an underdiagnosed neurocutaneous vasculopathy comprising small and medium-sized arteries, with an estimated incidence of 4 per million per year with a median age of 40 years. Its etiology is poorly understood, although autoimmune and thrombotic mechanisms have been proposed. An autosomal recessive condition of SS with CERC1 mutations (encoding adenosine deaminase 2) has been described. 

SS is characterized by central nervous system manifestations (headaches, multiple strokes, cognitive impairment), persistent livedo racemosa, hypertension, cardiac valvulopathy, and less frequent renal and ocular involvement. SS is classified according to the presence of Antiphospholipid (APL) antibodies in two groups: SSAPL+ and SSAPL-.

In patients with $SS_{A P L}$, it is important to consider other causes of thrombophilia, as in a recent series, 27% of patients who underwent thrombophilia testing had positive results. Patients with $SS_{A P L}$ present with thinner branching livedo macules, have a higher frequency of thrombocytopenia, seizures, and chorea. Patients with $SS_{A P L}$ present with a higher number of strokes before diagnosis. The treatment recommendations differ for patients with $SS_{A P L}$ and $SS_{A P L^+}$. For early stages of $SS_{A P L}$, regular monitoring with brain imaging is recommended, and in case of prodromic symptoms, prescription of low-dose aspirin. After an ischemic event, antiplatelet medications are the first-line treatment. For $SS_{A P L}$ patients, similar management recommendations are suggested initially, but in the event of arterial thrombosis anticoagulant therapy is recommended. This difference is based on two retrospective series. Francès et al. followed 46 patients (19 $SS_{A P L}$ and 27 $SS_{A P L^+}$) for six years. Authors highlight that among $SS_{A P L}$ patients, those who received anticoagulants had significantly fewer strokes than those on antiplatelet therapy. However, in $SS_{A P L}$ subgroup there were no differences in the number of strokes regardless of therapy. Bottin et al. followed 53 $SS_{A P L}$ patients for twenty years and found no significant differences in ischemic events between these two therapies. Nevertheless, the recently published series by Starmans et al. raises questions regarding these recommendations. In this retrospective study of 53 patients (14 $SS_{A P L}$ and 39 $SS_{A P L^+}$) with 21 years of follow-up, some patients were treated with antiplatelet therapy and some with anticoagulation, regardless of APL titers. During follow-up, patients with oral anticoagulation had significantly longer disease-free survival, as the time to first stroke recurrence in this group was twice as long as those receiving antiplatelet therapy (46 vs. 26.5 months, respectively). The authors recommend initiating antiplatelet therapy and switching to oral anticoagulation therapy early after any recurrent ischemic episode.

Our case report emphasizes that an extensive workout is needed in these patients given the higher risk of concomitant thrombophilia. The association between SS and Protein S deficiency has been previously reported. Also, our case shows that antiplatelet therapy may not be sufficient for disease control in $SS_{A P L}$ patients (Table 1). Given the importance of preventing early onset dementia, direct-acting oral anticoagulants – which have demonstrated similar efficacy to vitamin K antagonists with lower risk of intracranial hemorrhage in patients with ischemic strokes and atrial fibrillation – should strongly be considered in symptomatic $SS_{A P L}$ patients.
